How are behavioural interventions delivered to children (5–11 years old): a systematic mapping review

Amberly Brigden, Roxanne Morin Parslow, Catherine Linney, Nina Higson-Sweeney, Rebecca Read, Maria Loades, Anna Davies, Sarah Stoli, Lucy Beasant, Richard Morris, Siyan Ye, Esther Crawley

ABSTRACT

Context Behavioural interventions are used to prevent, manage and treat a wide variety of conditions including obesity, diabetes, chronic pain, asthma and emotional difficulties. There has been inadequate attention to the delivery of behavioural interventions to younger children (5–11 years old).

Objective Our objectives were to describe the characteristics of behavioural interventions for children aged 5–11 years.

Data sources We searched five databases: CINAHL, EMBASE, PsycINFO, MEDLINE and Cochrane Library, from January 2005 to August 2019.

Study selection The inclusion criteria were (1) children aged 5–11, (2) cognitive and/or behavioural interventions, (3) randomised controlled trials and (4) 2005 onward. Two researchers independently identified studies for inclusion.

Data extraction Two researchers independently extracted data from eligible papers.

Results The search identified 10,541 papers. We extracted information on 117 interventions (from 152 papers). Many of the interventions were categorised as complex. This was particularly true for clinical populations; 78.7% were delivered to both the child and parent, and 33.9% took place across multiple settings, typically health and school settings. Most (70.9%) were ‘First Wave’ (behavioural) interventions, and few (4.3%) were ‘Third Wave’ (characterised by metacognition, acceptance and mindfulness). Thirty-nine per cent used interactive techniques (play, arts, story and/or games). Purely digital and paper-based interventions were rare, but around a third used these tools as supplements to face–face delivery. There were differences in interventions for younger (5–7 years) and older (8–11 years) children.

Conclusions Interventions designed and delivered to children should be developmentally sensitive. This review highlights characteristics of interventions delivered to children 5–11 years old: the involvement of the child’s parent, using behavioural (rather than cognitive) modalities, using interactive techniques and some interventions were delivered across multiple settings.

INTRODUCTION

Health in childhood lays the foundations for health across the lifespan. Behavioural interventions are used to prevent, manage and treat a range of health conditions in childhood. Behavioural interventions targeting lifestyle behaviours, such as a healthy eating and physical activity, can prevent obesity, dental problems and osteoporosis. Behavioural interventions can support the management of long-term health conditions such as attention deficit hyperactivity disorder (ADHD), asthma, diabetes, chronic pain and cystic fibrosis. By promoting medication adherence, monitoring of health markers (eg, insulin and blood pressure) and engagement in condition-specific health behaviours. In some cases, behavioural intervention can be used to treat a condition, as in depression and anxiety, where the treatments tackle the maladaptive cognitions and behaviours that underlie the disorder.

Behavioural interventions (‘First Wave’) are based on the theory that all behaviours are learnt (through classical and operant conditioning) and that maladaptive behaviours can be changed using principles such as...
reinforcement, modelling, graded tasks and habit formation. Cognitive-behavioural (CBT, ‘Second Wave’) interventions are based on the principle that thoughts, feelings, physical sensations and actions are interconnected; individuals are supported to identify negative/unhelpful patterns in their cognitions, emotions, behaviours, physical sensations and supported to adopt more adaptive patterns. The ‘Third Wave’ of cognitive-behavioural interventions are characterised by techniques such as metacognition, acceptance, mindfulness, compassion and spirituality.

While behavioural interventions are commonly used in adolescent populations, less is known about the appropriate or effective ways to deliver interventions in younger, primary-school-aged children (5–11 years). Inadequate attention has been paid to designing/adapting interventions for the specific developmental stage of this age group, and comparatively fewer trials evaluating them in this younger age group.

Theory should be used when developing interventions; when designing interventions for children, this means considering development theory. Younger children have distinct physical, emotional, social and cognitive developmental characteristics. Younger children (under seven) are pre-logical and their thinking is dominated by perception. From the age of seven onward, children start to think logically, but until age 12, they are still limited to concrete rather than abstract thought processes. In line with cognitive development, children hold more basic beliefs about illness (“When you leave the window open, your blankets get cold which can make you a little bit sick”) and magical thinking about illness. Children are more reliant on caregivers. Parents/carers are typically the gatekeepers to recognising their child’s health needs, accessing services and implementing/overseeing health interventions. Children are also more reliant on caregivers at school, relying on teachers to support the management of their health condition.

A better understanding of the characteristics of behavioural interventions for children will be helpful for researchers developing and evaluating interventions, as well as clinicians implementing them. Mapping reviews are useful when synthesising information from a broad field of study, covering a large volume of literature. This study aims to ‘map’ behavioural interventions designed for younger primary-school-aged children (5–11 years old) to describe the way they are delivered to this age group in terms of recipients, modality, setting, mode and techniques of delivery.

**METHODS**

**Design**

We carried out a mapping review to answer the question: “how are behavioural interventions delivered to children aged 5–11?”.

**Search strategy**

The search strategy was developed with a University of Bristol data specialist. It included keywords and MeSH headings for (1) children aged 5–11, (2) cognitive and/or behavioural interventions, (3) randomised controlled trials, (4) intervention starting in the developmental stage of childhood (5–11 years). The search strategy was refined to focus on the most relevant studies according to the following headings: (1) children aged 5–11, (2) cognitive and/ or behavioural interventions, (3) randomised controlled trials. Searches were limited to studies published between 2005 and 2019.

**Participants/population**

Interventions designed for children aged between 5 and 11 years at entry to study. Interventions designed for children aged between 5 and 11 years at entry to study. Interventions delivered directly to the child and indirectly (ie, delivered by a proxy parent). All conditions/diseases or health behaviours.

**Intervention**

Any behavioural intervention (First, Second or Third Wave) aiming to change behaviour with a view to changing health outcomes or health behaviours (physical and mental health).

**Context**

Any setting.

**Time**

From 2005 to 2019. The UK’s Increasing Access to Psychological Therapies initiative was established in 2005; this was characterised by an expansion in the provision and evaluation of psychological therapies, largely CBT.

**Study type**

RCTs. Published in peer-reviewed journals and available in English.

**Exclusion**

Populations including children aged 5–11 years, but also spanning a wider age range (eg, 5–16 years). Participants with developmental delays as defined by the ICD-10. This review aimed to look at how interventions were delivered to the developmental stages of childhood (5–11 years). Children 5 to 11 years old with developmental delays would not be at a typical 5–11 year developmental stage.

Interventions that were not cognitive and/or behavioural (eg, surgery, medications etc).

Not restricted by setting.

Any study prior to the year 2005.

Studies that were not RCTs, eg, observational cohort studies and case reports.

We use the term ‘parent’ to refer to the primary caregiver/caregivers within the home.

CBT, cognitive-behavioural therapy; RCT, randomised controlled trial.
trials (RCTs) and (4) 2005 to present (online supplementary appendix A). The search was carried out on relevant databases: CINAHL, EMBASE, PsycINFO, MEDLINE and the Cochrane Library (August 2019).

**Screening**

Titles and abstracts (stage one) and full-text papers (stage two) were double screened against inclusion/exclusion criteria (table 1) using the data management platform Covidence. Reasons for exclusion were recorded at stage two. Discrepancies at both stages were discussed and resolved in meetings by reviewers. If the full text did not contain the information needed, we made two attempts to contact authors by email. If information was not provided, the study was excluded.

**Data extraction and synthesis**

Data were independently extracted by two researchers and conflicts resolved in regular meetings. We extracted characteristics of the population and intervention as described in table 2. We created categories for these based on existing taxonomies/coding systems or through an inductive process.

**Quality assessment/risk of bias**

We believe that there are no quality assessment tools for mapping review methodology. Further, given the large

volume of studies in this review, it was not feasible to carry out quality assessment.

**Patient and public involvement**
We did not involve patients or the public in our work.

**RESULTS**
The search identified 10541 papers. In total, 5583 were excluded at the title and abstract review stage, and 1975 were excluded at the full-text review stage. The most common reasons for exclusion at full text were wrong age (n=1070), not an RCT (n=577) and wrong paper type (protocol, abstract, presentation etc; n=206).

One hundred and fifty-two papers were eligible for the mapping review. The PRISMA diagram is displayed in figure 1.

Of the 152 citations, 21 interventions were described across two or more papers, and eight papers included two different active interventions. Therefore, in total we extracted data from 117 interventions.

**Population characteristics**
*Populations:* 56 interventions (47.9%) targeted clinical populations; 41 (35.0%) targeted healthy populations; 19 (16.2%) targeted at-risk populations. One intervention was for healthy population, with a more intensive component for a subset of at-risk participants. Figure 2 displays the characteristics of intervention for each population.

*Age:* 72 interventions (61.5%) included both younger (5–7 years old) and older (8–11 years old) children. Twenty-eight (23.9%) included older children only and 17 (14.5%) included younger children only. Figure 3 displays the characteristics of intervention for these different age groups.

*Condition/behaviour:* 54 interventions (46.2%) targeted lifestyle behaviours (diet, physical activity, dental care, hand washing, injury prevention, sexual health, substance use); 41 (35.0%) were for social–emotional–behavioural presentations (anxiety, conduct/opposition disorder, trauma, depression, behavioural problems); 14 (12.0%) were for neurodevelopmental disorders (ADHD); 8 (6.8%) were for physical symptom management/treatment (bladder/bowel dysfunction, asthma, cystic fibrosis, pain, sleep disorder).

**Intervention characteristics**
*Recipients:* 75 interventions (64.1%) involved parents. Of these, 66 (88%) involved both parent and child, and 9 (12%) were parent only. Considering the younger children (5–7 years old), all interventions for clinical populations included parents. None of the interventions for children 8–11 years old were delivered without the child (figure 3). Fifty-nine interventions (78.7%) for clinical and at-risk populations involved parents.

Six of the RCTs were designed to compare the effectiveness of child versus parent involvement; exploring parents exclusively versus parents and child or child exclusively versus child and parent.

In some cases, a rationale for including parents was not provided. Where a rationale was provided, this included a theoretical rationale (social cognitive and parenting theories); the role of parents in controlling the child’s...
Figure 2 Characteristics of interventions, displayed by population. ADHD, attention deficit hyperactivity disorder; SEB, social-emotional-behavioural.

For some of the intervention components, the child was a passive recipient; the components were based on changing the environment around the child to change their behaviour. Twenty-five (21.4%) used environmental restructuring (ie, changing the physical environment to change behaviour) including the provision of healthy foods, sports sessions and equipment, moving a TV out of the child’s bedroom, provision of fluoride toothpaste and offering recreational activities. Examples of structuring the social environment

social and physical environment, and providing reward and reinforcement, and a developmental rationale, that is, the child’s limited cognitive capacity.

Modality: 83 interventions (70.9%) used a ‘First Wave’ behavioural approach, 51 (43.6%) used ‘Second Wave’ cognitive-behavioural approaches and 5 (4.3%) used a ‘Third Wave’ approach. There were no ‘Third Wave’ interventions for younger children (5–7 years old) (figure 3).

Figure 3 Characteristics of interventions, displayed by age.
included activities designed to change the ecology of the classroom environment and activities changing the school-wide climate.

Some intervention components required the child to be an active participant in therapy. They were required to engage in the intervention through learning psychoeducational material, engaging in self-monitoring, self-regulation and self-management.

**Intervention setting:** 71 interventions (60.7%) took place within a school setting. Fifty-three (45.3%) took place in a clinical setting and 17 (14.5%) took place in a community setting (including the fire service, police, girl guides/Scouts, and other unspecified organisations).

“curriculum in social-emotional learning... Each curriculum unit focuses on a specific grade-appropriate children’s book and begins with a book reading and discussion, ensuring that students understand the primary themes of the story” <sup>67</sup>  
“Muck Monster... a metaphor for negative self-talk” <sup>72</sup>  
“A Cognitive–Behavioral Pain Management Program called “Stop the pain with Happy-Pingu” <sup>58</sup>  
“Taming Sneaky Fears CBT Group Program manualized child treatment consisted of... stories, games, and activities designed specifically to teach cognitive-behavioral strategies” <sup>27</sup>  
“trauma narratives conveyed through storybooks with pictures created by students, ‘courage cards’ tailored to each student, use of published children’s books to introduce certain topics” <sup>74</sup> |

| To impart knowledge and encourage behaviour change | “nutrition education intervention aimed at increasing the consumption of fruits and vegetables... A graphics package was developed using cartoon characters (The Bash Street Kids DC Thomson & Co. Ltd) which were used as a theme in the communication and promotional materials” <sup>45</sup>  
“internet based oral hygiene intervention... key characters in the cartoons... developed superhuman powers by brushing their teeth... The Teeth Chiefs had a series of adventures with nasty germ-like monsters, called the ‘Plackos’, that rot children’s teeth. Design of the cartoons was guided by a set of behaviour change principles” <sup>66</sup>  
“obesity prevention programme... characters with whom the children identify. Children work closely with the character most like them to help them to change their behaviours” <sup>98</sup> |

| **Characters as stand-alone interventions** | “a pictorial story about going to the dentist on pain perception, situational anxiety and behavioral feedback during dental treatment” <sup>73</sup>  
“The child could carry out a version of the treatment (s)he had just undergone on the glove puppet. The application of this behaviour management technique immediately after the dental visit was used to enable the child to become active and so reduce anxiety” <sup>75</sup> |

| Games | Reward-based games | “star charts and... star pyramids to track their dietary intake and frequency of a variety of physical activities. Small rewards, such as stickers, were given for returning completed charts” <sup>28</sup>  
“a three week chart, with the child’s name on it, to put up in the bathroom so their child could add a sticker each morning and evening when they brushed their teeth” and “a guide for parents on how to use rewards” <sup>82</sup>  
“The Good Behaviour Game...The teacher posted basic classroom rules of student behaviour, and during a particular game period all teams received a reward if they accumulated four or fewer infractions of acceptable student behavior” <sup>93</sup>  
“Match Game... tokens would be given for an accurate self-evaluation... Tokens retained at the end of each session were exchanged for reward coupons which could in turn be exchanged for a daily group reward and a monthly individual home-based reward” <sup>89</sup> |

| Games to Improve Health Knowledge | “Top Grubs” a card game based on trumps with pictures of food, that such higher scoring (trumping) foods are the healthier ones <sup>20</sup>  
“An oral health education interventions involving ‘contests on oral health knowledge’ <sup>62</sup>  
“‘Quiz time’... Review knowledge, understandings, and skills developed throughout the program” <sup>91</sup> |

| Group interactive activities | Group interventions used play, arts and game-based activities such as:  
treasure hunts, material printing  
puppet play, competitive games  
map drawing and photographic techniques  
and other unspecified games” <sup>95</sup> |
brownies and local gyms/recreation centres). Twenty-seven (23.1%) of all interventions, and 19 (33.9%) of interventions for clinical populations, were delivered across multiple settings.

**Mode of delivery:** The most common mode of delivery was face–face (n=113, 96.6%), either in a group (n=75), individual setting (n=17), a mixture of both (n=19), or group versus individual delivery as comparator arms in the RCT (n=2). Three were purely digital interventions, or additional digital components (n=14, 12.0%). Eighty-face–face with additional printed material (n=26, 22.2%) or additional experiential component such as sports sessions, cooking workshops or field trips.

**Techniques of delivery:** 42 interventions included some form of play, arts, story and/or game-based technique (table 3); this equated to 39.3% of the interventions with a child recipient (ie, excluding those delivered to parents only).

NARRATIVE: Storytelling and characters were integrated into CBT programmes, used in behavioural/psychoeducational interventions, and two studies used stories or characters as stand-alone interventions. Forty interventions (34.2%) used reward principles, and many implemented this in the form of a game; children could earn points, prizes, stickers and treats for adhering to the treatment plan. In most interventions, caregivers (parents, teachers) were responsible for structuring the reward system. Some interventions used quizzes and card games to promote knowledge about health behaviour or health management. This was either as a stand-alone intervention or within a multicomponent intervention.

**Complexity:** 70 interventions (59.8%) were categorised as complex. The dimensions of complexity are summarised in table 4.

**Effect of interventions**

Forty-eight papers failed to define a primary outcome, and a further 13 papers did not provide data on effectiveness/efficacy because they were RCT pilot studies, process evaluation studies or other types of paper which did not report effectiveness data. As such, we were able to assess the primary outcome for 56 interventions; of these, 26 interventions led to an improvement on the primary outcome, 23 did not lead to improvement on the primary outcome and 7 had mixed results (there was more than paper reporting on the intervention). Figure 4 displays the results of interventions with a primary outcome, presented by modality (note that an intervention may use more than one modality if it is multicomponent). There were a similar number of effective and non-effective behavioural interventions. We did not identify any effective third-wave interventions.

ADHD, attention deficit hyperactivity disorder.
DISCUSSION

Summary of findings
This is the first systematic review to map and describe how behavioural interventions are delivered to children aged 5–11. Parental involvement in interventions was common (64.1%). Many of the interventions were categorised as ‘complex’; they contained several components, including multiple modes of delivery, were delivered to more than one recipient and took place across different settings. This was particularly true for interventions delivered to clinical populations, where the majority were delivered to both the child and parent (78.7%), and around a third (33.9%) took place across multiple settings, typically a healthcare setting and school setting. Most (70.9%) were ‘First Wave’ behavioural interventions, and few (4.3%) were ‘Third Wave’. Many of the interventions integrated interactive techniques. Purely digital and paper-based interventions were rare, but around a third used these tools as supplements to face-to-face delivery. There were potentially differences in interventions for younger (5–7 years) and older (8–11 years) children; interventions for younger children tended to have more parental involvement (all of the clinical interventions for children aged 5–7 years included parents), did not use ‘Third Wave’ approaches and more commonly used reward/reinforcement techniques. All interventions for older children involved the child as a recipient compared with 82.4% of the interventions for younger children. However, because of the small number of interventions for children 5–7 years old, it is hard to draw firm conclusions.

Strengths and limitations
This review was not restricted to a specific health condition/behaviour. This allowed us to explore the principles of delivering interventions to younger children across a broad spectrum of health conditions/behaviours. We provided the interventions’ modality (First, Second or Third Wave), but because of the size of the review it was not feasible to code specific techniques used in more detail, for example using the Behavioural Change Technique Taxonomy. We excluded observational cohort studies for pragmatic reasons; including observational studies to the data set would have made analyses unwieldy. While observational studies may have added some richness to the data, there were sufficient data in the RCTs to answer the research questions. Including only RCTs allowed us to focus on interventions most likely to be adopted into clinical care and those that were reported with higher quality. However, there was still wide variation in how interventions were reported, according to level of detail and terminology used. As such, there was a degree of subjectivity in data extraction of elements such as modality (eg, behavioural vs CBT) and standardisation (manualised vs non-manualised treatment). To mitigate this, we carried out independent double extraction, using established coding systems and taxonomies (for modality, mode of delivery, age, and population type) and developed additional guidance documents.

Implications in context of literature
When designing and delivering interventions for children, they should be developmentally sensitive and rooted in developmental theory. Theory on cognitive development states that children tend to be limited to concrete rather than abstract thought, as well as less sophisticated illness beliefs. As such, concrete interventions focused on behavioural recommendations are more appropriate. Consistent with this, behavioural interventions were most common, though we did find that a similar number of effective and non-effective behavioural interventions. CBT requires logical analysis and abstract thinking, and there are caveats on how this should be used with children. We found fewer CBT-based therapies. There were only five third-wave interventions, and none were delivered to children under the age of 7. The limited use of these approaches is consistent with existing literature stating that third-wave approaches may not be appropriate for children, and concepts such as metacognition are likely to be beyond the cognitive capacities of this younger population. Alternatively, the low number of papers may be because this is a relatively new approach with children; research is in its early stages but is gaining interest, with examples of RCTs currently underway. The papers included in this review suggest it may be possible to adapt third-wave concepts, to make them developmentally appropriate for younger children, using exercises, visuals, characters and drawing to make these abstract concepts more concrete, as well as providing briefer interventions. From the few studies in this review, we did not identify any effective third-wave interventions. At this stage, third-wave approaches for children are novel and untested, but worthy of more investigation to evaluate

Figure 4 The number of effective and non-effective interventions, displayed by modality.
effectiveness, and explore how they can be delivered to children in a developmentally sensitive way.

Interactive methods are suited to the cognitive developmental stage of children 5–11 years old. Children can find it difficult to process abstract information and express themselves verbally. Art-based methods can provide an opportunity to communicate visually, and stories can include visual supports and are engaging for children. Play is an important part of childhood; it is enjoyable, rewarding, and can support children to learn skills and behaviours. Many interventions reviewed here used arts, play and games-based techniques to engage and teach children. Developmental theory also highlights the importance of caregivers; in childhood, caregivers play a key role in structuring the child’s environment and shaping the child’s behaviour. Children are embedded in the family context. Equally, children may spend many hours a day at school in the care of teachers. In this review, many studies included parents and schools, and parental involvement was greatest for the younger children.

Although many interventions included in this review appeared informed by developmental theories, many did not explicitly report how developmental theory guided intervention design. Intervention development and reporting would be improved by doing so.

In this review, there are many examples of interventions which target the same behaviour/condition for similar populations but have been developed independently. However, guidance for developing interventions recommends using a systematic review to identify existing evidence-based interventions and refining these to investigate optimal delivery, rather than developing a novel one.

This review highlights issues about trial design in this field. A clearly defined and pre-specified primary outcome is important; it reduces the risks of selective reporting of outcomes and false-positive from analysing too many outcomes. However, we found that around 40% of the interventions failed to specify a primary outcome.

Future research
Tools to aid the design and reporting of interventions do not sufficiently capture characteristics important for delivery to children; the Behaviour Change Techniques Taxonomy does not sufficiently cover interactive techniques or delivery via parent proxies. Future work to incorporate these techniques may enhance these tools.

In this mapping review, we identified areas of interest around parental involvement, the use of digital interventions to supplement face–face delivery and setting (delivery in both school and clinics). Future systematic reviews could focus on these areas.
