Accepted 7 June 2021

ABSTRACT

Background Children undergoing surgery and their parents are at risk of developing post-traumatic stress reactions. We systematically reviewed the literature to understand the prevalence of this issue, as well as potential risk factors.

Methods We conducted a systematic review and meta-analysis, using PubMed, PsycInfo, Web of Science and Google Scholar, with searches conducted in February 2021. Papers were included if they measured post-traumatic stress in children and/or parents following paediatric surgery and were excluded if they did not use a validated measure of post-traumatic stress. Data were extracted from published reports.

Findings Our search yielded a total of 1672 papers, of which 16 met our inclusion criteria. In meta-analysis, pooled studies of children estimated an overall prevalence of 16% meeting criteria for post-traumatic stress disorder post surgery (N=187, 95% CI 5% to 31%, $I^2=80\%$). After pooling studies of parents, overall prevalence was estimated at 23% (N=1444, 95% CI 16% to 31%, $I^2=91\%$). Prevalence rates were higher than those reported in the general population. Risk factors reported within studies included length of stay, level of social support and parental mental health.

Interpretation There is consistent evidence of traumatic stress following surgery in childhood which warrants further investigation. Those delivering surgical care to children would benefit from a raised awareness of the potential for post-traumatic stress in their patients and their families, including offering screening and support.

INTRODUCTION

Traumatic psychological stress reactions can develop in individuals who experience frightening or life-threatening events.¹ Post-traumatic stress reactions incorporate a range of psychological symptoms. Diagnostic criteria exist to capture these experiences, namely in the form of post-traumatic stress disorder (PTSD) and acute stress disorder (ASD). Symptoms of PTSD and ASD include re-experiencing, avoidance, hyperarousal

What is known about the subject?

- ▶ When a child undergoes surgery, the child and/or their parents can experience psychological distress as a result.
- ▶ Some children and parents can experience surgery as a traumatic event and subsequently develop symptoms of post-traumatic stress disorder (PTSD).
- ▶ There may be risk factors which could help identify families who are more likely to develop such difficulties.

What this study adds?

- ▶ The pooled prevalence of PTSD in children undergoing surgery was 16% and 23% in parents, which is higher than the general population.
- ▶ Cases where the surgery is more complex, or associated health conditions are serious or life-threatening, appear to increase the risk of PTSD.
- ▶ Cases of longer admissions, where the parent reported additional mental health difficulties, or families with less social support were more likely to report PTSD.

and negative alterations in cognitions and mood.^{2–4}

Research suggests that lifetime exposure to at least one traumatic event is quite common at around 90%.⁵ Lifetime prevalence of PTSD in adults has been estimated to be between 6.8%⁶ to 9.8%.⁵ In children, studies indicate that 14%–43% of children and adolescents are exposed to at least one traumatic event in their lifetime and that up to 15% of those exposed go on to develop PTSD, with girls being at higher risk than boys.⁷ It is clear therefore that psychological trauma is a significant issue in both child and adult populations.

PTSD has been linked to a range of psychological and interpersonal difficulties, including comorbid mental health difficulties such as depression, substance misuse, suicidal ideation,⁸ eating disorders,⁹ anxiety disorders¹⁰ and poor family relationships.¹¹ Given that traumatic stress reactions can have such an impact, it is important that services can effectively identify and support families in cases where they may be exposed to trauma. Research is limited, however, and there is a lack of understanding of the risk that surgery poses in terms of the development of post-traumatic stress.

Emerging evidence suggests that children undergoing surgery are at risk of developing traumatic stress reactions post surgery,^{12–15} as are parents of children undergoing surgery.^{16 17} To date, there is only sporadic evidence of, and no consensus on, the rates of traumatic stress development following surgery, or if any risk factors, such as parental stress,¹⁸ might increase the chances of such difficulties occurring.

An understanding of post-traumatic stress following surgery in childhood is important, to allow for opportunities to mitigate risks or provide appropriate psychological support. Although there is emerging evidence, the literature on this topic has not yet been systematically synthesised. We therefore conducted a systematic review and meta-analysis using Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidance of the literature on: (1) what is the evidence for psychological trauma following surgery in children and their parents and (2) what factors are associated with trauma responses in the same groups.

METHOD

Search strategy and selection criteria

We conducted a systematic review with a separate meta-analysis with an overall summary estimate from available data. We searched the literature using PubMed, Web of Science and PsycInfo databases.

We used the following search terms: (Psychological distress OR anxiety OR depression OR mental OR trauma OR traumatic OR post-traumatic stress OR acute stress) AND (children OR adolescent OR family OR sibling OR parent OR carer OR paediatric OR pediatric) AND (surgery OR surgical OR operation OR hospital OR procedure OR anaesthetic). Searches were performed in February 2021 by two independent reviewers who then conferred to agree inclusion and exclusion.

We also performed a separate search using Google Scholar and by searching references of included texts. Google Scholar searches were conducted using the search criteria 'PTSD surgery children' and 'Acute stress disorder surgery children'. We also screened reference lists of included studies for additional papers missed in initial searches.

A priori inclusion criteria were: (1) studies which reported on psychological trauma in children undergoing any type of surgery; (2) studies which reported on

psychological trauma in parents of children undergoing surgery; (3) observational or intervention studies and (4) papers in all languages. Exclusion criteria were: (1) studies which did not use a validated measure; (2) studies which reported other mental health variables if there was not an explicit measure of trauma and (3) literature reviews other than systematic reviews.

Data analysis

Studies were extracted to Endnote which was used to remove duplicates. Quality of studies was assessed using the Newcastle-Ottawa Quality Assessment Scale (NOS), adapted for use with cross-sectional studies.¹⁹ Studies can achieve an overall rating of a maximum of 10 stars. Each study in the review was assessed by one researcher (SK) scored appropriately. A selection of studies was blindly assessed by another researcher (DPT), with ratings compared and found to match.

Meta-analysis

Prevalence rates reported in studies for PTSD were pooled in meta-analysis using STATA (V.16) for studies reporting prevalence in: (1) children and (2) parents. The metaprop command was used, with a random effects model using the Freeman-Tukey double arcsine transformation, with pooled estimates and 95% CIs reported.²⁰ Sensitivity analyses were performed by removing studies with greatest bias (<5 total NOS Score). Where available, data were extracted from individual studies to perform meta-regression to identify potential moderator variables on effect sizes across pooled studies.

Patient and public involvement

Patients and members of the public were not consulted regarding the development of the research question or the research design.

RESULTS

Initial searches yielded a total of 1671 papers, 609 of which were identified as being duplicates and subsequently removed. The abstracts of the remaining 1062 papers were examined for relevance. In total, 149 papers were then retrieved and reviewed for inclusion. A total of 16 papers were included in the final review. [Figure 1](#) shows a summary of the search and study selection process. [Table 1](#) provides a summary of the studies included.

There was variation in the type of surgery involved in each study, with the most common being cardiac (five studies). In total, six (38%) studies investigated traumatic stress just in child participants, while eight (50%) studies reported data on parents only. A further two (12%) studies reported on both children and parents concurrently.

Most studies (13) reported whether participants met diagnostic or clinical thresholds for PTSD or ASD, as per the cut-off ranges of the respective measures used. One study gave a breakdown of PTSD symptoms without

Figure 1 Study selection flowchart.

reporting the number of participants who reached threshold for diagnosable PTSD. The majority of studies (12) provided data regarding correlating or risk factors associated with higher symptoms of traumatic stress.

Prevalence findings in children and young people

In total, six studies suggested that at least some children had developed PTSD or ASD symptoms after surgery.^{13–15 21–23} One study by Liu *et al*²² included participants who had been involved in a natural disaster prior to surgery, which was not controlled for and may have inflated rates of traumatic stress. Another study did not report overall rates of traumatic stress, but did report that high numbers (56%) of children displayed difficulties with specific PTSD symptoms, for example, flashbacks.¹³

The four remaining studies which reported overall prevalence of PTSD symptoms at least 3 months post surgery were pooled in meta-analysis (see figure 2) for a total of 187 children. All included studies had a NOS Score ≥ 5 . Heterogeneity was high ($I^2=80\%$). Overall pooled estimate of prevalence was 16% (95% CI 5% to 31%). Available data from studies allowed meta-regression of type of surgery (cardiac vs other), mean age of children and sex proportion in samples as predictors of prevalence, with none showing significant association (data not shown).

Prevalence findings in parents

In total, 11 studies reported rates of traumatic stress symptoms in parents.^{16 17 21 23–30} All of these studies reported that at least some parents self-reported symptoms consistent with full PTSD diagnostic criteria. The 11 included studies which reported prevalence of PTSD symptoms at least 3 months post surgery in parents were

pooled in meta-analysis for a total of 1444 parents from all studies (see figure 3). Heterogeneity was high between studies ($I^2=91\%$). Overall pooled estimate of prevalence of PTSD was 23% (95% CI 16% to 31%). Removal of studies with lowest NOS Score did not improve heterogeneity or affect overall pooled estimate significantly. Available data from studies allowed meta-regression of type of surgery, mean age of children and parents, sex proportion of children and parents and parental further education level as predictors of prevalence and none were found to be statistically significant (data not shown).

Findings on potential influencing factors within studies

Several studies conducted additional analyses to investigate the presence of factors which were associated with or predicted PTSD development in children and parents. A number of variables were reported. Four studies showed that length of stay in hospital was positively associated with PTSD.^{15–17 25} Some authors¹⁷ suggested that this finding was explained by length of stay in hospital reflecting illness severity in the child. Others proposed that children who spend longer in hospital will be exposed to higher levels of accumulative trauma.¹⁵ This assumes the entire hospital experience to be traumatic, including associated procedures and recovery, over and above the surgery itself. One study which just found this association in fathers suggested that the longer the hospital stay the more parents may struggle to meet the demands of work and family commitments while the child remains in hospital.²⁵ This explanation would suggest that the depletion of resources contributes to traumatic stress development or that parents who cannot work due to the caring for a hospitalised child may face financial or other burdens which increase stress and decrease ability to cope.

It is likely that a combination of factors relating to the duration of hospital stay during and post surgery contribute to the development of traumatic stress in children and parents. Most of these risk factors are consistently recorded in clinical care and could easily be used to identify those more in need of additional psychological support.

Several studies reported that different factors relating to the severity of the surgery, complications within the surgery or severity of the child's illness can contribute to the development of traumatic stress. For example, studies reported that more invasive procedures,^{23 29} complications such as the requirement for mechanical ventilation^{16 27} or the severity of the child's condition²⁸ were all associated with higher PTSD. These findings related to both children and parents.

In three (19%) studies, associations were found between parental mental health and child traumatic stress.^{14 21 23} Specific difficulties that parents reported were PTSD and depression. These findings suggest that the distress and ability to cope of parents can play a significant role in the mental health and traumatic stress of children following surgery.

Table 1 Overview of studies by surgery type

Author	Measures	Sample (N)	Quality rating	Type of surgery	Summary of findings
A. Cardiac surgery					
Connolly <i>et al</i> ¹⁵	DISC	Children (43)	5	Cardiac.	12% of children met diagnostic criteria for PTSD post surgery. 12% had symptoms but did not meet full criteria. Length of hospital stay was the only significant predictor of postoperative PTSD ($r=0.19$).
Franich-Ray <i>et al</i> ²⁴	ASDS	Parents (135)	7	Cardiac.	27% of parents met diagnostic criteria for ASD 1 month post surgery. Dissociative symptoms were the most frequently endorsed symptom cluster.
Helfricht <i>et al</i> ²⁵	PDS	Parents (233)	4	Cardiopulmonary bypass.	15% of parents met diagnostic criteria for PTSD post surgery. The rate was 12% at 6-month follow-up. Length of hospital stay significantly related to PTSD (fathers only). Being of non-native nationality was related to increased PTSD.
Landolt <i>et al</i> ²⁶	PDS	Parents (232)	3	Cardiopulmonary bypass.	25% of parents met criteria for PTSD at discharge. 34% had partial PTSD. Those with full or partial PTSD were significantly more likely to report lower mental health-related quality of life.
Stokes <i>et al</i> ²⁷	PCL-S; PAT	Parents (31)	5	Cardiac.	7% of parents met diagnostic criteria for ASD at 2 years post surgery, as did 18% of those lost to follow-up. Depression, anxiety and operative complications of prolonged mechanical ventilation were significantly associated with PTSD.
B. Mixed surgery					
Ben-Ari <i>et al</i> ³²	UCLA-PTSD; PTSDSSI; PAT; PDS	Children and parents (235)	7	Various, for example, urology, ENT.	Higher parental distress, stress regarding social support and parental concerns regarding sibling problems predicted child PTSD.
Ben-Ari <i>et al</i> ²¹	UCLA-PTSD; PDS	Children and parents (88)	7	Various, for example, urology, ENT.	10% of children met full PTSD diagnostic criteria 5 months post surgery. 12% of parents met criteria for full PTSD. There was a significant correlation between child and parent PTSD ($r=0.417$).
Ben-Amitay <i>et al</i> ¹⁴	CPTS-RI	Children (39)	5	Various, for example, otolaryngology, orthopaedics.	21% of children scored in the mild-moderate range for PTSD. At 6 months post surgery, child PTSD was positively associated with mother's depression scores ($r=0.52$).

Continued

Table 1 Continued

Author	Measures	Sample (N)	Quality rating	Type of surgery	Summary of findings
Liu <i>et al</i> ²²	ASDS	Children (105)	4	Various.	54% of children met full diagnostic criteria for ASD post surgery. Participants were victims of the Wenchuan earthquake of 2008.
Nagata <i>et al</i> ²⁸	IES-R	Parents (145)	6	Various, for example, inguinal hernia, biliary atresia.	20% of parents met criteria for PTSD. Factors associated with higher PTSD levels were state and trait anxiety, current condition of the child ($r=-0.351$), likelihood of future operations ($r=0.297$), distance from support ($r=0.229$) and disease severity ($r=0.214$).
Scrimin <i>et al</i> ²⁹	PSSI	Parents (154)	5	Day, minor and major surgery, for example, appendicitis, craniotomy.	16% of parents met full criteria for ASD post surgery. Traumatic stress was higher in major surgery groups compared with day surgery and in those with less social support and fewer years of education.
C. Other surgery					
Beaudoin <i>et al</i> ³⁰	PCL-5	Parents (168)	7	Neurosurgery.	45% of parents met criteria for PTSD. Parents of children who had greater than three surgeries had higher levels of PTSD symptomology. PTSD rates were also influenced by the type of neurosurgical procedure the child underwent and their diagnosis.
Ben-Ari <i>et al</i> ²³	PTSDSSI; PCASS; PDS	Children and parents (30)	5	Congenital melanocytic nevi removal.	33% of children met criteria for PTSD 4 months post surgery. Invasive medical procedures, family resources and parental distress predicted 40% of the variance in distress. For parents, 63% rated surgery as a traumatic event and 27% met PTSD diagnostic criteria.
Ari <i>et al</i> ¹³	PTSDSSI; PCASS	Children (79)	6	General paediatric not specified.	Five months post surgery, 56% of children had significant symptoms of re-experiencing, 30% avoidance and 33% hyperarousal. 26% of parents reported being very concerned about the child's fears since the surgery.
Bevilacqua <i>et al</i> ¹⁶	IES-R	Parents (170)	5	Congenital malformation.	48% of parents met criteria for PTSD 6 months post surgery. Length of hospital stay was a significant predictor of PTSD ($F(5, 156)=11.745$). Surgery and condition-related anomalies and days of mechanical ventilation were associated with PTSD.

Figure 2 Forest plot of proportions of children meeting criteria for post-traumatic stress disorder >3 months after surgery with pooled estimates of overall prevalence with 95% CIs (with dotted line also showing the pooled overall weighted mean estimate of prevalence = 16%; and ES = effect size).

The direction of these associations is not necessarily known and could feasibly operate in either direction, that is, parental mental health leads to children being more likely to develop traumatic stress or where children develop traumatic stress, parents are more likely to suffer with their own mental health. These findings are potentially important in helping to identify those who may benefit from additional support.

Some factors relating to social and family support appear to be important when considering traumatic stress following surgery. One study found that when lower levels of family social support were reported using the Psychosocial Assessment Tool II,³¹ children were more likely

Figure 3 Forest plot of proportions of parents meeting criteria for post-traumatic stress disorder >3 months after surgery with pooled estimates of overall prevalence with 95% CIs (with dotted line also showing the pooled overall weighted mean estimate of prevalence = 23%; and ES = effect size).

to report traumatic stress.³² In this study, social support included psychological help, financial support, daily help and help with childcare. Authors suggested that a lack of such resources made it more difficult for children to cope with the stress of the surgery and hospitalisation, not least because it might mean parents were less available to support them. In another study, parents had higher levels of traumatic stress if they reported being far away from their support network or had fewer social contacts around the time of the surgery.^{28 29} Additionally, one study found that being a non-native nationality was related to symptom severity and that mothers who used the social services provided by the hospital presented with more severe symptoms of acute PTSD.²⁵ Collectively, these findings suggest that social support is an important factor in the development of surgery-related traumatic stress in both children and parents.

DISCUSSION

This systematic review and meta-analysis of the literature examined post-traumatic stress reactions in children and parents following surgical intervention in a child. In meta-analysis, pooled estimates of prevalence of post-traumatic stress were 16% in children and 23% in parents. Past epidemiological research has suggested that 8% of children in the general population will develop PTSD by 18 years, a figure which rises to 25% in those who experienced at least one trauma in their lives.³³ Lower prevalence figures have been reported for adults who have experienced trauma.³⁴ This review therefore suggests that paediatric surgery may lead to an increase the risk of PTSD, which has implications for screening and service provision for children undergoing surgery and their families.

We found evidence that a range of psychological and social factors might increase the risk of post-traumatic stress within studies. We did not find evidence for moderating variables in meta-regression once studies were pooled, though there was inconsistent reporting of potential influencing variables across studies thus potentially limiting power. The most commonly reported risk factor in studies was the length of time spent in hospital. This may be explained either by those being in hospital for longer being more exposed to potentially traumatic events, are more unwell, or have had a more serious surgical intervention. It is likely that patients who have experienced complications or multiple procedures are also in this group.

Research suggests that individuals with more social support are less likely to develop chronic PTSD symptoms.^{35–40} There was some evidence to support this in the current review, with several studies reporting a lack of family and social support being associated with traumatic stress in both children and parents. These findings may also relate to duration of hospital stay for children who spend longer in hospital are more likely to miss out on support from extended family or friends; or parents

who spend significant amounts of time visiting or staying with a child in hospital may be less able to access social support during this period.

Our search had a number of strengths. The literature search was systematic and robust, including rigorous searches of multiple databases and sources. A priori search terms were used, with agreed inclusion and exclusion criteria for selecting suitable studies. Throughout the search, two researchers were used to cross-reference studies in terms of the inclusion/exclusion criteria, as well as is the quality rating of studies. This will have reduced the risk of error and increased reliability. Our review was necessarily narrow in focus, investigating post-traumatic stress reactions solely. However, children and parents may well present with other mental health (eg, anxiety) or behavioural concerns following surgery, the investigation of which was beyond the scope of this review. In young children particularly, indicators of post-traumatic stress may manifest in ways that are not captured in standard trauma measures, such as via behavioural difficulties. It is important, therefore, that services consider wider aspects of mental health, behaviour and well-being when considering the possible impact of paediatric surgery.

The interpretation of findings is limited by the cross-sectional design of studies, meaning that firm conclusions about the cause of traumatic stress in patients are hard to draw. For example, we found that duration of hospital stay was associated with higher levels of traumatic stress. However, there are several associated variables that might explain this, such as whether patients perceive their situation to be life-threatening,^{23 29 41–43} which might be more likely in children who spend longer in hospital as they are more likely to have undergone more serious surgery or experienced complications. Further, it was not possible to separate the impact of the surgery specifically from the incident or illness which led the child requiring surgery, which may itself be experienced as traumatic, for example, an accident leading to injury. None of the studies we found controlled for this issue.

None of the studies in the review included a measure of traumatic stress at baseline (before surgery) and again post surgery. This is important as a potential source of bias, since the absence of a baseline measure makes it hard to conclude whether the surgery directly preceded the onset of traumatic stress reactions or whether traumatic stress was already present prior to surgery. Additionally, no studies in the review included control groups against which levels of traumatic stress could be compared. Because we found a number of studies reporting proportions, we were able to perform a meta-analysis. The heterogeneity was high, however we did use a random effects model and performed sensitivity analyses by removing studies with the greatest bias.

Many studies did not have long-term follow-up and only measured traumatic stress directly following surgery. Some research suggests that as many as 56% of individuals who develop PTSD will spontaneously recover within 5 months of onset¹⁰ and so findings in the short term may

not have been maintained. None of the studies included details of whether participants received appropriate interventions for traumatic stress which may have influenced measures at follow-up. Future research in this area should include follow-up measurements to improve our understanding of the long-term persistence and effects of traumatic stress post surgery.

Future studies should include baseline, presurgery measures of trauma symptoms and traumatic event checklists where participants are asked to report types of traumatic events they have experienced. This will help to clarify the role of surgery in the development of traumatic stress reactions. Our study provides evidence of sufficient levels of traumatic stress following paediatric surgery to warrant the evaluation of interventions to support children and families where the child undergoes surgery. Clinical guidelines recommend a period of active monitoring for mild symptoms for a period of 4 weeks, as a way of supporting individuals in the weeks following a trauma.⁴ Future research could investigate report on the implementation of such interventions and on their effectiveness.

CONCLUSIONS

There is consistent evidence in the literature of post-traumatic stress following surgery in childhood which warrants further investigation. Cases where the surgery is more complex, or the associated health condition is serious or life-threatening, appear to increase the risk of traumatic stress reactions. Several other risk factors have been identified, which may guide services in screening those who may be most at risk. These include cases where the child is in hospital for a longer period, the family are lacking in social support or a parent is suffering with mental health difficulties or high levels of stress.

Those delivering surgical care to children would benefit from a raised awareness of the potential for post-traumatic stress in their patients and their families. Services should also consider using screening measures to help identify families more at risk and to offer support where required. This is particularly relevant in case of service disruptions such as during the current pandemic, where screening for traumatic stress and other mental health difficulties is challenging. Those interventions may provide support to those who report difficulties or are more at risk.
